

welcome to the brighton data forum! thank you for coming!

we are a networking, socialising, and skilling sharing community of data professionals in the broadest sense of all of those words.

we cover all things data: data analysis, data science. data engineering, strategy, governance, ai, data ethics, data storytelling, and more. we're comprised of professionals from executives to juniors, and welcome participation from students and enthusiasts. our home is on meetup.com, we hold regular events on the last wednesday of the odd numbered months, irregular events whenever we can, and we have a slack workspace where we continue the conversation between events. we are proud to be a part of the silicon brighton community.

from zero to query

a sql primer

oskar 2023-03-06

this is one of our irregular events. today we want to get you started on using sql.

sql - a fundamental tool for the data professional

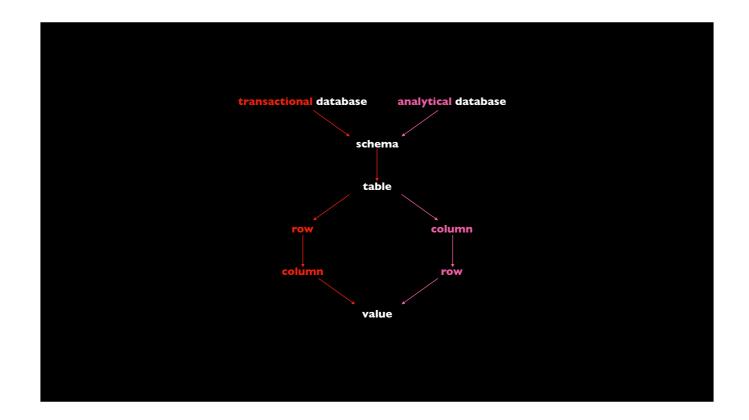

- database management
- data pipeline engineering
- data modeling
- data designing
- big data (parallel, distributed)
- data querying
- data analytics

you signed up. you came here, i presume you are already motivated to learn sql so i won't try to motivate you further that you can benefit from knowing sql. but it is worth knowing about sql, that it is fundamental for various data professionals, whether they are for instance database managers, data pipeline engineers, data modelers, schema designers, data reporters, data analysts, data scientists. it is the ubiquitous, default language used to interact with any big data tool.

sql - a fundamental tool for the data professional

- database management
- data pipeline engineering
- data modeling
- data designing
- big data (parallel, distributed)
- data querying
- data analytics

today we focus on the latter two aspects, using sql for querying and analytical computations.

sql's natural environment is in databases, where tabular data, that is rectangular tables are the central concept. a database contain schemas, and each schema comprises of a set of tables.

- in a transactional database, write speed, low-latency and high availability are paramount. tables are comprised of rows and each row is a list of column-values.
- in analytical databases, tables are comprised of columns, each column is a list of row-values.

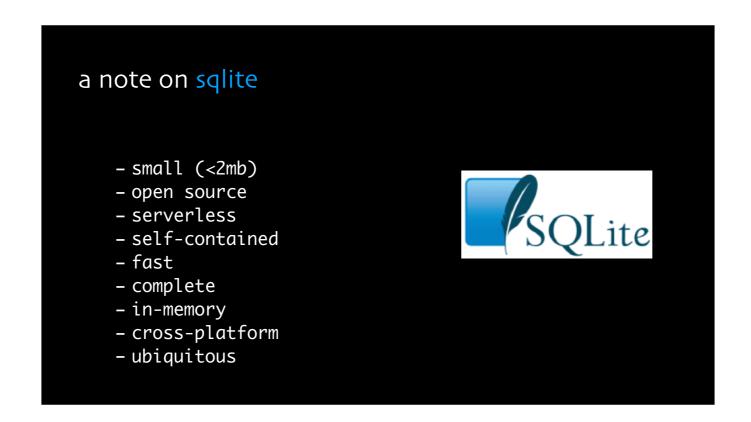

in reality, a production database is comprised of a lot more components than this, there are users, user groups, access controls, procedures, functions, schedulers etc, etc.

data definition	data management	data querying	data control	transaction contro
to operate on entire tables	to operate on table values, rows, columns	to fetch data from tables	to control access to schemas + tables	for transactional atomicity, dev
CREATE	INSERT	SELECT	GRANT	COMMIT
DROP	UPDATE		REVOKE	ROLLBACK
ALTER	DELETE			SAVE POINT
TRUNCATE				

sql is a collective term for 5 components: a data definition language, data management language, data querying language, data control language, and a transaction control language.

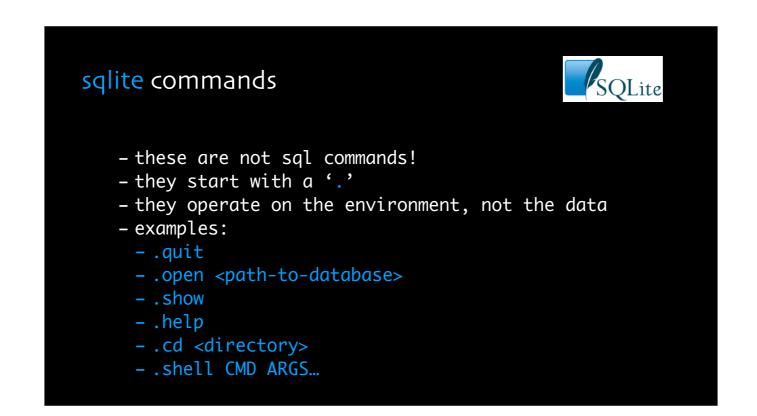

data definition	data management	data querying	data control	transaction control
to operate on entire tables	to operate on table cells, rows, columns	to fetch data from tables	to control access to schemas + tables	for transactional atomicity, dev
CREATE		SELECT	GRANT	COMMIT
DROP	UPDATE		REVOKE	ROLLBACK
ALTER	DELETE			SAVE POINT
TRUNCATE				

this workshop is aimed for beginners and we are going to ignore most of that. today we focus one the data querying language, which is the feature of sql used for extracting information from database tables (querying) and for performing analytical computations. today, you only need to learn to use a single command, the SELECT statement. this really lies at the heart of sql. it is what any user of sql needs to know, so it is an obvious starting point.

we will need an interpreter, a program that reads your sql statements and converts it into actions onto a database, to retrieve the desired data. tonight we will be using sqlite to access the training database with.

it is an obvious choice: sqlite is the minimal, **the simplest** application to query a database. it is the most popular database tool in the world, and it is built into countless applications. and i hope you all have sqlite already installed on your machines, but it is quick to install if not.

you should know a minimum commands for sqlite. note that these are not sql commands, they operate on the interpreter itself, the sqlite environment. (whereas sql commands define, query, or perform analytical computations on the database).

sqlite commands start with a period. the first one you should know is .quit which quits the app.

.open followed by the path to a database in the sqlite format will pull in the database and tell sqlite that your sql commands/statements should operate on this database.

.open data/sqlite-sakila.db
.header ON
.mode qbox
.show
.tables

after starting up sqlite,

you will want to run these commands like so. don't forget the dot in front! try it now.

first, you open up the training database inside sqlite.

then, some useful but optional command for display purposes.

and finally list all the available tables with the dot-tables command.

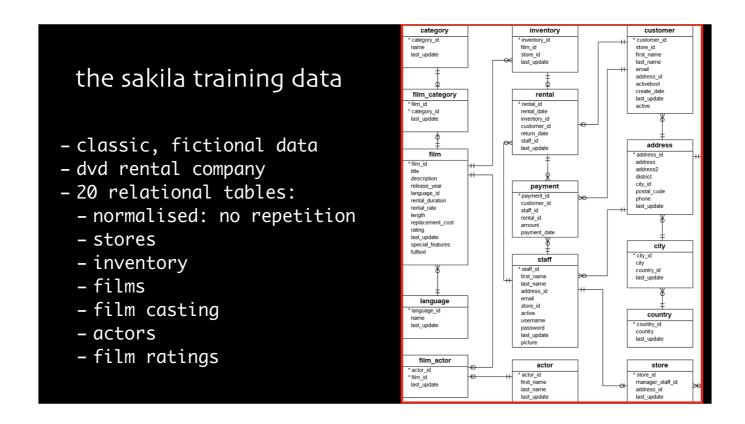

```
.tables
     sqlite> .tables
                           film
     actor
                                                 payment
     address
                           film_actor
                                                 rental
                           film_category
                                                 sales_by_film_category
     category
                                                 sales_by_store
                           film_list
     city
     country
                           film_text
                                                 staff
                                                 staff_list
                           inventory
     customer
     customer_list
                           language
                                                 store
     sqlite>
```

you should be seeing a list of 21 tables like this, please let a nearby instructor know if you are not getting this response, as nothing else will make sense if we don't all start from the same starting point.

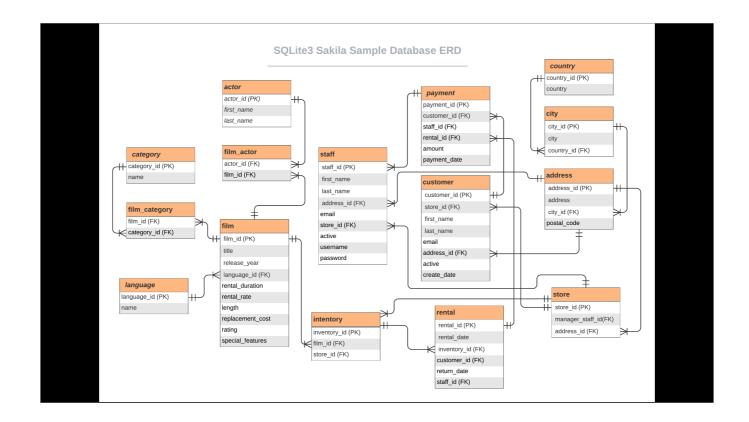

ok? that is a lot of tables! we won't need all of them but we will be working with many of these.

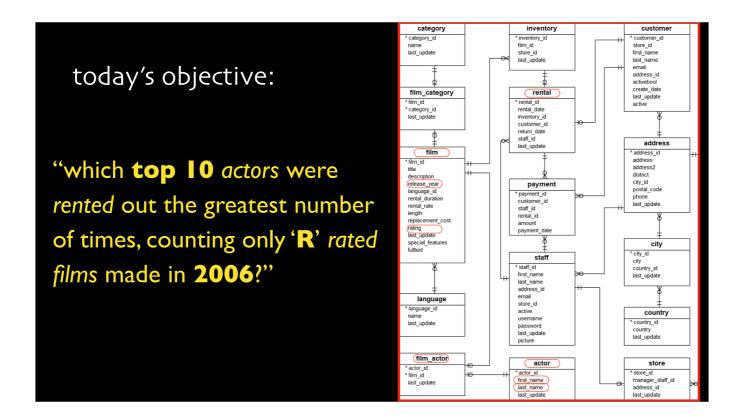

next, a note on the training data. this is a classic database made for training purposes. if you are familiar with r or python you will know these classic datasets: the titanic dataset, iris, mtcars, penguins, etc. in sql there are a few of those too. this one is called sakila and describes the database of a chain of video rental stores. yes, this is an outdated concept. bear with me.

sakila is an example relational database. the tables relate to each other as this entity relationship diagram describes.

you will find this entity relationship diagram in the repo under img/.

now consider this dilemma: imagine you are running a chain of dvd rental stores, and you are deciding how much stock of upcoming films to procure. you have no data on the popularity of the new films since they are not out yet, but you do know their cast. and you have noticed that films with certain actors are rented out more than others. some actors might be rented out a lot more than others even if their individual films are not the most popular films. so you ask yourself: "who are the actors that get rented out the most number of times? i must ensure i will get plenty of stock of the upcoming films featuring those actors." the answer to this question lies in the data, but in order to conjure it out requires a specific query. the rest of today is about generating the query that answers this question.

```
- these run on the database
- they end with a ';'
- you can add comments with '-- a comment'
- they operate on the data tables
- example:
- SELECT {columns} FROM table; -- a&b
```

now. a note about sql commands. they do not start with a period. they always end with a semicolon. you will undoubtedly forget the semicolon at some point today. that's ok. we are here to point it out. but start now getting used to adding a semi colon to every sql statement. (just the sql statements, and not the sqlite commands!)

here is the question and the list of sql *components* required to answer the question. here, they are presented in a pedagogical order, from the most basic, to the more complex.

by the end of this workshop, you will be able to assemble these components together to construct a sql query to answer any such question of the data in your database.

we have seen what tables are available in the training database. next, we start asking ourselves what data these tables contain. and here is where the venerable SELECT statement comes in. the output of a SELECT statement is a *table* of results.

at a minimum we must specify 2 pieces of information to the select statement.

- 1) from which table we want to query, and
- 2) which of those table's columns we want returned.

for the latter, we can use the asterisk wildcard (indicating all available columns) a la "SELECT * FROM a_tablename;"

```
SELECT ... FROM ...;

- SELECT * FROM {tablename};
-- returns all columns and all rows from a table

- SELECT name, category_id FROM category;
-- returns columns name and id (in that order) of each category

- SELECT a.first_name AS name FROM actor a;
-- creates an alias for table actor, fetches column first_name as name

- SELECT rental_rate + replacement_cost AS total_cost FROM film;
-- returns the 'total_cost' of renting, then replacing a film

- SELECT DISTINCT first_name FROM actor;
-- returns all the first names in the actor table, no duplicates
```

this is the minimal SELECT statement: here are examples on how to fetch information from tables. go ahead try these commands or versions of them, replacing the table and column names with tables you found in the previous step.

note

- 1. every command ends with a semicolon
- 2. -- comments your code
- 3. you can alias results and table names

```
SELECT (aggregate function) FROM ...;

- SELECT COUNT(*) AS num_records FROM actor;
-- returns the number of rows in table actor, names the output 'num_records'

- SELECT COUNT(DISTINCT rating) FROM film;
-- returns a count of distinct values in the rating column

- SELECT AVG(replacement_cost) AS avg_cost FROM film;
-- returns the average replacement cost of a film

- SELECT AVG(rental_rate) AS average_rental_rate FROM film;
-- returns the average rate of rental from film table

- SELECT MAX(s.sale_cost) AS highest_value_sale FROM sales s;
-- returns the highest value sale from sales

- SELECT MIN(length) AS shortest_length FROM film;
-- returns the length of the shortest film
```

in addition to extracting each value from each row, we can also request sql deliver us aggregates of all the rows, e.g. counts, sums, averages, min, max, etc. try these examples. each should output a single value. note that you can either ask for a column value, OR for an aggregate value, but it does not make sense to mix the two.

some of our tables have a large number of records. we don't want to overwhelm ourselves or our screens with hundreds, thousands, millions of rows. that is not useful to see, we can use a LIMIT clause within our SELECT statement to achieve that.

```
SELECT ... FROM ... LIMIT ...;

- SELECT * FROM {table} LIMIT {n};
-- returns {n} unspecified rows of all columns from {table}

- SELECT * FROM sales LIMIT 5;
-- returns 5 unspecified rows of all columns from sales

- SELECT title, release_year FROM film LIMIT 15;
-- returns 15 unspecified rows of two columns from sales table

- SELECT rental_id, rental_date FROM rental LIMIT 10;
-- returns region id and region name for 10 unspecified rows
```

here are examples on how to fetch limited information from tables. go ahead try these commands or versions of them, replacing the table and column names, note that limit 5 just tells sql that we want no more than 5 rows. we have not specified in any way which 5 rows we want. they could be any rows in the table. sql gets to decide which rows to serve us, and it normally chooses whatever rows it can produce in the fastest time. note that in many database systems

we will now start to get more specific about what information we want to extract from the tables. the first limitation we applied was by selecting specific *columns*. then we learned how to only retrieve a limited number of unspecified rows. now, let us select *specific rows* from the table, namely rows where some specific column values are found, the way to do that in sql is by adding a WHERE clause, in the SELECT statement, *right after* the FROM clause.

```
SELECT ... FROM ... WHERE ... [LIMIT n];

- SELECT * FROM {table} WHERE {column}={expression};
-- returns only rows where the value in {column} equals {expression}

- SELECT * FROM table_name WHERE column1<>{expression};
-- returns only rows where the value in column1 is not {expression}

- SELECT title AS film_name, rental_rate FROM film WHERE rental_rate<=1.0;
-- returns titles of films whose rental price is at most £1

- SELECT name FROM items WHERE item_price>=10 LIMIT 8;
-- returns 8 of the items whose price is greater or equal to £10
```

we will now start to get more and more specific about what information we want to extract from the tables. the first limitation was selecting specific columns. now let the next limitation we set on the data be about selecting specific rows. the way to do that is by adding a WHERE clause in the SELECT statement. try it. also note that you can still add a LIMIT clause as well.

here are the comparison operators you can use to make a condition. some notes:

- 1. if you are used to c, r, python, and some other programming languages you may have expected equality being represented as '==', but that is not the case for sql. in sql "a=b" evaluates to true if a and b are equal.
- 2. '<>' and '!=' are synonyms for "not equal".

comparison operators

operator syntax	meaning
{column} = {expression}	column value is equal to expression value
<pre>{column} <> {expression}</pre>	column value is not equal to expression value
<pre>{column} != {expression}</pre>	column value is not equal to expression value
{column} < {expression}	column value is less than expression value
{column} <= {expression}	column value is less than or equal to expression value
<pre>{column} > {expression}</pre>	column value is greater than expression value
{column} >= {expression}	column value is greater than or equal to expression value
{column} IN ({exp1}, {exp2},)	column value is one of 'exp1', 'exp2',
{column} LIKE '%expr%'	(string) column contains substring 'expr'
{column} BETWEEN {exp1} AND {exp2}	{exp1} <= column value <= {exp2}

- 1. IN (),
- 2. LIKE "%",
- 3. and BETWEEN...AND are special, sql specific, and useful comparison operators.

```
SELECT ... FROM ... WHERE ...;

- SELECT * FROM rental WHERE rental_date BETWEEN '2005-11-01' AND '2005-01-01';
-- returns only rentals occurring in dece 2005

- SELECT * FROM sales WHERE region_id IN (14,56,43);
-- returns only sales in regions with id 14, 56, or 43

- SELECT * FROM region WHERE region_name LIKE '%new%';
-- returns only regions whose name contains 'new'

- SELECT DISTINCT postal_code FROM address WHERE postal_code LIKE '97%';
-- show all the postal codes that start with '97'
```

here are some examples of how to use BETWEEN, IN, LIKE:

```
but i only want the most extreme rows!

    "which top I0 actors were rented out
    the greatest number of times, counting
    only 'R' rated films made in 2006?"

- SELECT {columns} FROM {table}
-+ LIMIT num;
-+ WHERE {a_condition}
-+ ORDER BY {columns}
-+ GROUP BY {columns}
-+ HAVING {a_condition}
-+ [INNER] JOIN {table_2} ON {col1}={col2}
```

next we introduce the ORDER BY clause to the SELECT STATEMENT. it simply specifies in what order we want our result table sorted.

say if we want the top 10 most expensive items we cannot just put that in a WHERE clause without knowing what the price of the 1th most expensive item is. so instead we can use another way to specify which records we want returned: by sorting the records by some criteria and then LIMITing the number of records to just a few of rows.

```
SELECT * FROM payment ORDER BY payment_date LIMIT 7;
--- return the earliest 7 payments in the payment table

- SELECT * FROM payment ORDER BY payment_date DESC LIMIT 7;
--- return the latest 7 payments in the payment table

- SELECT * FROM payment ORDER BY amount DESC LIMIT 5;;
--- return only the top 5 highest payment amounts from the payment table
```

ok let us try it. first, let us take a look at the payment table. the first command orders the table by the payment date, and returns only the 7 earliest records. the next one is almost the same, with only one small difference. to order a table in the opposite order we we ORDER BY column DESC (for descending order, ascending is default and assumed).

```
how can i aggregate groups of rows into a single row?

"which top 10 actors were rented out
the greatest number of times, counting
only 'R' rated films made in 2006?"

- SELECT {columns} FROM {table}
-+ LIMIT num
-+ WHERE {a_condition}
-+ ORDER BY {columns}
-+ GROUP BY {columns};
-+ HAVING {a_condition}
-+ INNER JOIN {table_2} ON {col1}={col2}
```

we will often want a summary of a table, e.g. the sum or an average of a column. we saw before how we could do that across all the rows in a table. very often we want to treat groups of rows as separate, isolated segments, and sum together some measure only among rows within the same segment. that is what the GROUP BY clause is for.

```
SELECT {col}, ... FROM ... GROUP BY {col};

- SELECT city_id, COUNT(*) AS num_address FROM address GROUP BY city_id;
-- return number of addresses in each city in address table

- SELECT rating, AVG(length) AS avg_len FROM film GROUP BY rating ORDER BY avg_len;
-- returns the average length of a movie in each rating category

- SELECT country_id, COUNT(*) AS num_cities
FROM city
GROUP BY country_id
ORDER BY num_cities DESC
LIMIT 5;
-- return top 5 country ids, by number of cities assigned to each
```

when you run a group by query, you do not get a response table with one row per row in the input. rather you get one row per segment, per group, per distinct value in the group by column. alongside each distinct value of the grouping variable, you can also get a summary of other columns. (recall the aggregate functions from above: SUM(), COUNT(), COUNT(DISTINCT), AVG(), MAX(), MIN().

```
how do i report only some aggregated groups?

"which top I0 actors were rented out
the greatest number of times, counting
only 'R' rated films made in 2006?"

- SELECT {columns} FROM {table};
- + LIMIT num
- + WHERE {a_condition}
- + ORDER BY {columns}
- + GROUP BY {columns}
- + HAVING {a_condition}
- + [INNER] JOIN {table_2} ON {col1}={col2}
```

when we want to aggregate over specific groups of rows, but are only interested in some of the outcomes we can filter on the aggregated rows (one row per segment or per category). for instance,

there is an actor's name in the actors table that is repeated. that is: two records in that table have the same first and last name. how to find a repeated name in the list? if you counted the number of films with each rating, but excluded from the output, ratings where counts.

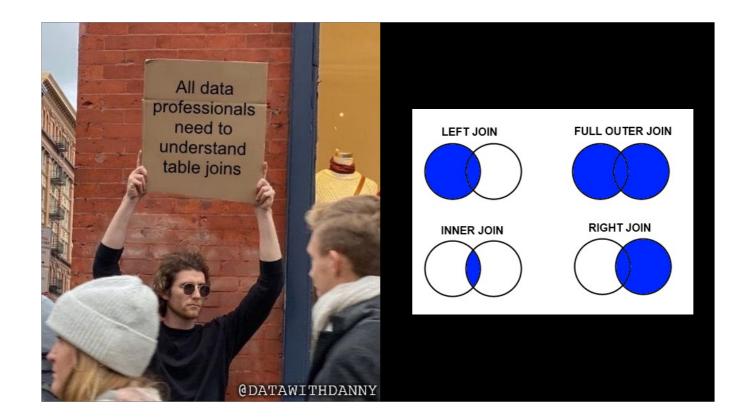

SELECT ... FROM ... GROUP BY ... HAVING ...;

- SELECT col1, COUNT(*) AS num FROM table GROUP BY col1 HAVING num>9;
 -- count instances of each value of col1, but only output rows with count>9
- SELECT rating, AVG(length) AS len FROM film GROUP BY rating HAVING len<115; -- the film rating categories with average length of film under 115 minutes
- SELECT actor_id, COUNT(*) AS n FROM film_actor GROUP BY actor_id HAVING n<15;
 -- which actor ids have appeared in fewer than 15 films?</pre>

HAVING clause is like a WHERE clause: it places a condition on the rows returned. but unlike WHERE clause, it does not filter the rows of the input table, but rather filters the rows of the aggregated table, before it is returned and can be used to filter out specific values of the aggregated values.

note that it doesn't make sense to include a HAVING clause in a SELECT statement that doesn't have aggregation functions..

often, the data we need is an amalgam of information spread across multiple tables. in order to get precisely the data we need, we must JOIN multiple tables. the join clause is the trickiest concept we will talk about today. let's take it slow.

there are multiple types of joins. which to use depends on what you want the output to be. you will most often encounter either left join or an inner join. you use a left join whenever you have a table that already has most of the information you need, but you need to add a column to that table with values from another table. an inner join is appropriate if the table you already have and the other table, share a unique and complete primary key.

consider these two tables, just the top few rows are shown. the first one lists a number of cities in the world. the second one lists countries.

note that one of the properties given for each city is the country it is in.

but it doesn't say the country name, just the id of the country, which is a look up key in the country table.

if we are interested in finding out which country that city called adana is in, we need to find the country with id '97'. that country happens to be turkey.

likewise 'aden' is in yemen. and so on and so forth. but we don't want to have to do the looking up. we want sql to do that for us.

you want to produce something like this. here is a hint on how to work use the JOIN clause: always picture what you expect and want the output to look like first, then write the code. make sure you have a clear image of what you are trying to achieve first.

city_id city country 1	city_id country 1 A Corua (La Corua) Spain 2 Abha Saudi Arabia 3 Abu Dhabi United Arab Emirates 4 Acua Mexico 5 Adana Turkey 6 Addis Abeba Ethiopia 7 Aden Yemen	we want this						
A Corua (La Corua) Spain	I A Corua (La Corua) Spain 2 Abha Saudi Arabia 3 Abu Dhabi United Arab Emirates 4 Acua Mexico 5 Adana Turkey 6 Addis Abeba Ethiopia 7 Aden Yemen	city-and-country						
2 Abha Saudi Arabia 3 Abu Dhabi United Arab Emirates 4 Acua Mexico 5 Adana Turkey 6 Addis Abeba Ethiopia 7 Aden Yemen	2 Abha Saudi Arabia 3 Abu Dhabi United Arab Emirates 4 Acua Mexico 5 Adana Turkey 6 Addis Abeba Ethiopia 7 Aden Yemen		city_ia	-	-			
3 Abu Dhabi United Arab Emirates 4 Acua Mexico 5 Adana Turkey 6 Addis Abeba Ethiopia 7 Aden Yemen	3 Abu Dhabi United Arab Emirates 4 Acua Mexico 5 Adana Turkey 6 Addis Abeba Ethiopia 7 Aden Yemen		ı					
4 Acua Mexico 5 Adana Turkey 6 Addis Abeba Ethiopia 7 Aden Yemen	4 Acua Mexico 5 Adana Turkey 6 Addis Abeba Ethiopia 7 Aden Yemen							
5 Adana Turkey 6 Addis Abeba Ethiopia 7 Aden Yemen	5 Adana Turkey 6 Addis Abeba Ethiopia 7 Aden Yemen							
6 Addis Abeba Ethiopia 7 Aden Yemen	6 Addis Abeba Ethiopia 7 Aden Yemen							
7 Aden Yemen	7 Aden Yemen							
8 Adoni India	8 Adoni India							
			8	Adoni	India			

now, it turns out that sql is brilliant at producing tables like that. the syntax magic to make something like this work all happens in an addition to the FROM clause.

so you have FROM table_a JOIN table_b ON table_a.key_column=table_b.key_column...

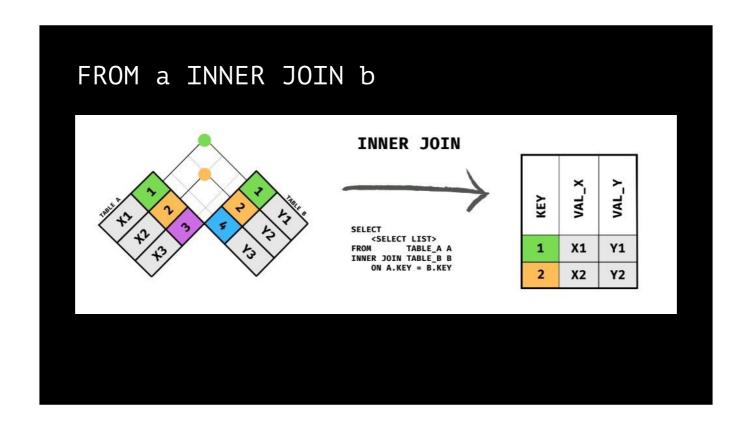

and here is the output of that

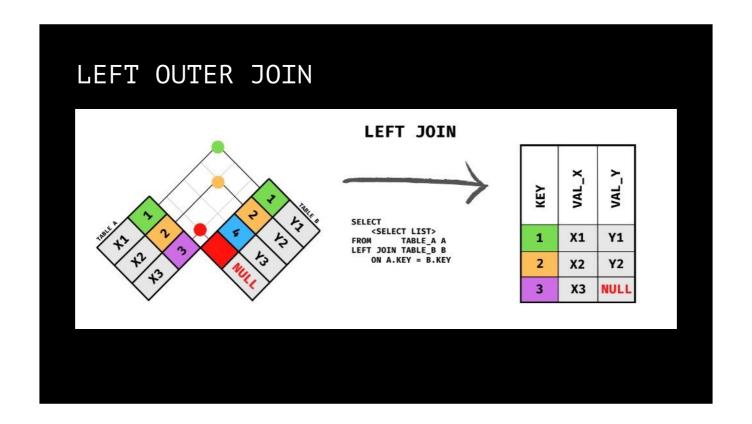

SELECT ... FROM a INNER JOIN b ON ...;

```
    SELECT a.city, b.country
        FROM city a
        INNER JOIN country b ON a.country_id=b.country_id
        ; -- output a table with city-country names
    SELECT f.title, f.length, l.name
        FROM film f
        INNER JOIN language l ON f.language_id=l.language_id
        WHERE rating='R'
        LIMIT 10; -- output a sample of films and the name of the language it is in
```

try it!

we just showed you an INNER JOIN. that is when between two tables only returns only the rows where the keys from both tables match. for our city + country table example, we are assuming that there is no city in that table with an associated country_id that does not exist in the country table. had that been the case, then that city would not occur in the output. likewise, if there were a country in the country table with a country_id that no city in the city table was associated with, then that record would no appear in the output of an INNER JOIN.

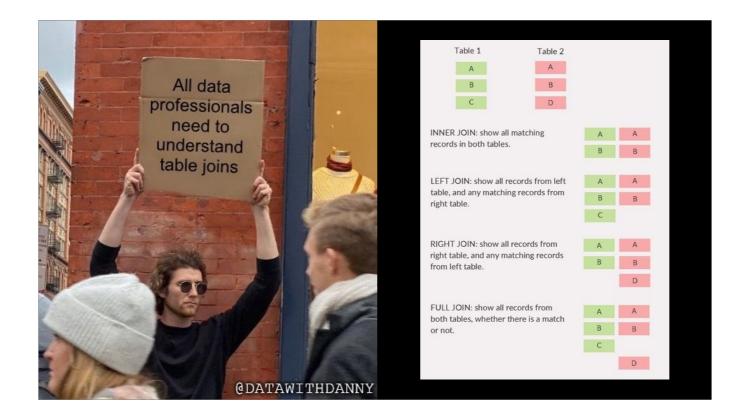

the left join is also known as the left outer join, and is very common.

FROM table_a LEFT JOIN table_b.

this method of merging tables treats the rows from table_a (the left hand table) with preference, and every row from table_a is guaranteed to be found in the output (whether or not it matches anything in table_b). the information in a row from table_b (right hand table) is only included if its key matches a row in the left hand table, otherwise it is ignored.

(i.e. if there were a country in the country list that no city in the city list belonged to, we would not include that country in the output).

the point is that joins can be tricky and often trip people up. be careful and always, always start by thinking careful about what the output should look like and what should happen if your key has duplicate instances in either table.

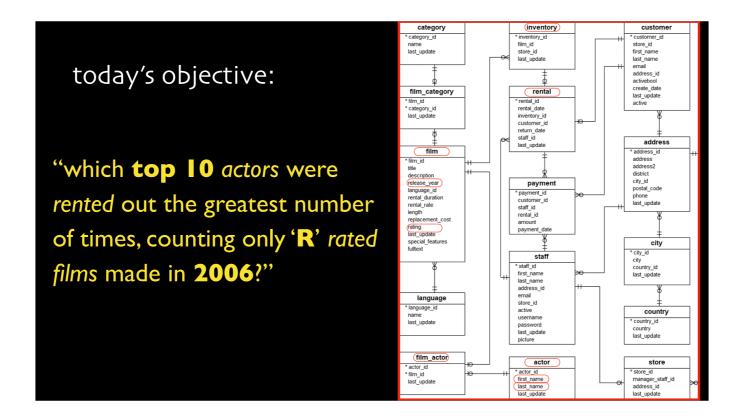

as you can see, joining tables is a crucial data skill. if you have a background in r, python, excel: you might call this by a different name: merge, mesh, vlookup. they are all related. now we just showed you inner join. it will only return rows for keys that are found in both tables.

there are multiple kinds of join. for a properly set up relational database, like we have, the inner join is most useful, that is because we can trust our primary keys to be unique and present in every row. if our database had some wonky data, with broken primary keys, primary keys missing or duplicated, we would need to be more careful. an inner join only returns rows where the join key value is found in both tables.

we also often use a left join. in a left join we ensure that all the rows that in the table on the left of the join clause are present, whether or not the corresponding key is found in the right hand table.

right joins are rarely if ever needed, you can just turn the join around as a left join.

there are other join types, but we will focus on these.

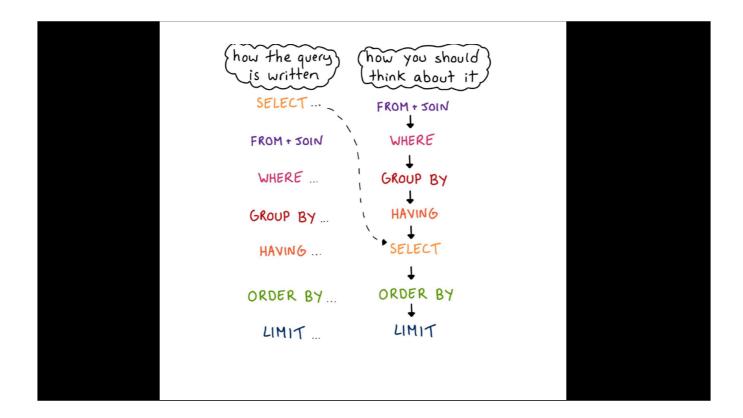

to answer the question at hand we are going to have to join the tables shown here: the actor table, the film_actor, the film table the inventory, the rental

```
how do i combine the components of a SELECT?

"which top 10 actors were rented out the greatest number of times, counting only 'R' rated films made in 2006?"

- SELECT {columns} FROM {table};
-+ LIMIT num
-+ WHERE {a_condition}
-+ ORDER BY {columns}
-+ GROUP BY {columns}
-+ HAVING {a_condition}
-+ [INNER] JOIN {table_2} ON {col1}={col2}
```

excellent. now we have covered **all the components that we need** to answer the question. the dql component of sql is only one statement, the SELECT command and the SELECT command really is this simple. all that remains is combining these components all in the particular configuration that gives us the right answer. sql is strict about the order in which the components are combined.

but the order that sql demands is not the same as the order we usually think about data transformations from source data to solution. follow the right hand side pathway:

- you start with a table, which you may join with another table to get a merged table,
- you then filter out some of the rows from that table,
- then you **group** the remaining rows into segments,
- then you filter out the segments that you want,
- then you **select** columns (the group categories and aggregations within each segment, computations on the columns etc) that you want in the output.
- and then you (optionally) **sort** the resulting table of segments.
- finally you (optionally) **trim** the output to the desired length.

that's simple! however, sql demands we arrange the components in the slightly different order as shown on the left hand column. the steps are all conceptually the same, and the output is the same, it is just the syntax that requires the SELECT clause in front of all the rest.

your turn! compose a query to answer:

"which top 10 actors were rented out the greatest number of times, counting only 'R' rated films made in 2006?"

that's it! now just work on the solution

```
hint: structure of the solution

SELECT
{} AS actor_name,
COUNT({}) AS num_rentals
FROM {table1}
INNER JOIN {table2} ON {join-condition}
INNER JOIN {table3} ON {join-condition}
INNER JOIN {table4} ON {join-condition}
INNER JOIN {table5} ON {join-condition}
WHERE {row condition1}
AND {row condition2}
GROUP BY {column1}
ORDER BY {column} DESC
LIMIT {num}
```

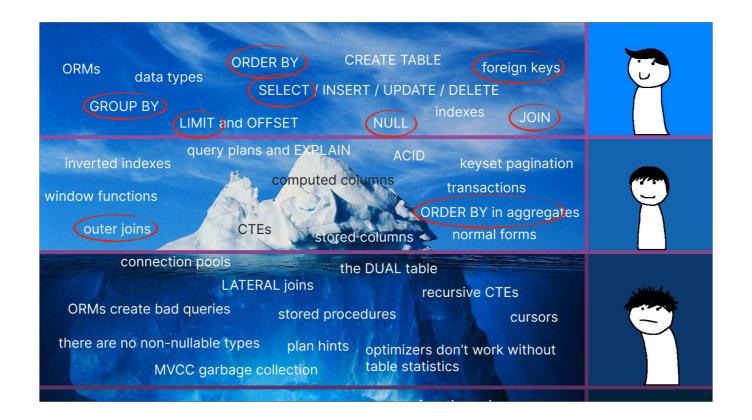

we have 15 more minutes. if you are finding the assignment hard, take a look at this structure. this is the structure of the query you must make. you just need to compose the expressions in place of the curly brackets.

you made it! congratulations! give yourselves a round of applause. you have learned a lot today: we covered how to query a database for quite specific answer, collecting information from across multiple tables.

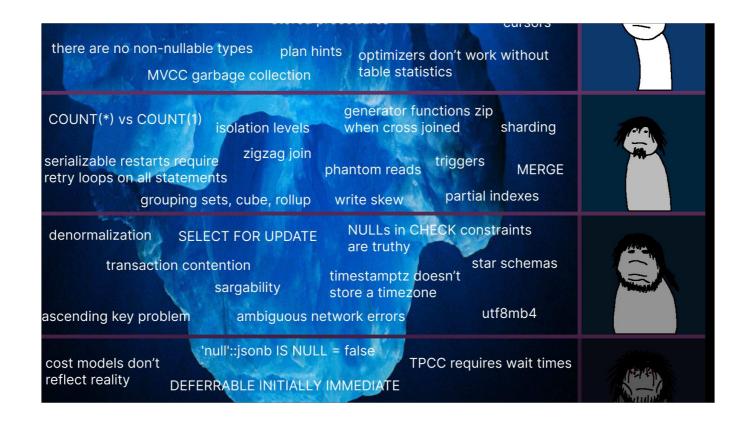

we hope that this workshop has sparked your curiosity about sql. if you keep digging you will find that sql has plenty more to explore. there is a lot more to sql than we were able to cover here.

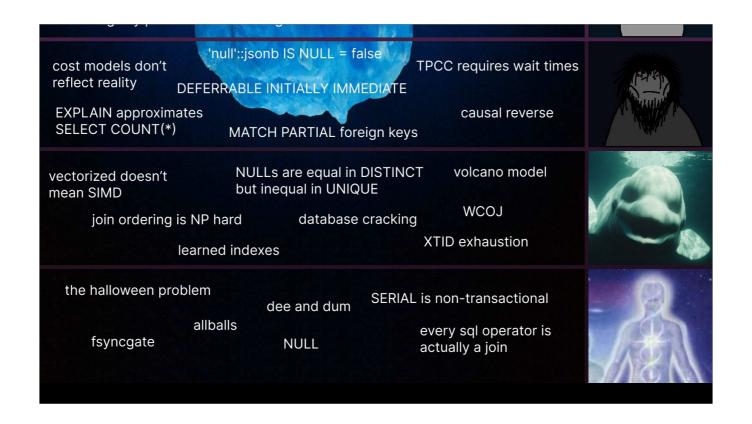

here are some of the topics covered today.

a sensible next step from here would be learn more analytics functions and how use something called window functions in sql, and common table expressions.

beyond that, you will find a lot of sql's power, usefulness, and ubiquity stems from how it handles the complexities of database management,

i have no idea what most of these mean. but i suspect that you will never run out of adventures to be had with learning sql!
